Enterobius vermicularis is an important human parasite which causes symptoms including anal itching, abdominal disturbance, appendicitis or chronic salpingitis, and sometimes involves colon and genital tract (Beaver et al., 1984). The eggs of *E. vermicularis* can not be detected easily by usual fecal examination and enterobiasis is not a common parasitic disease in present years, but there have been limited reports on the infection status in general population. To evaluate the status of *E. vermicularis* infection in primary school children, we visited a primary school in agricultural area located in Tangjin-gun, Chungchongnam-do in December, 1998. The survey was done by the adhesive cellotape anal swab method from 9 to 11 in the morning. Each grade consisted of one classroom and the examination was carried out with all children who attended that day.

Of the 189 examinee, 28 (14.8%) were egg positive. The infection rate in 46 kindergarten children was 26% and infected children were found from every grade.

Three months after treatment with albendazole, four (14.3%) out of 28 infected children still remained infected with *E. vermicularis*. Through this survey, we were able to determine that *E. vermicularis* infection is still prevalent among children in rural areas of Korea.

**Enterobius vermicularis** egg positive rate in a primary school in Chungchongnam-do (Province) in Korea

**Abstract:** The egg positive rate of *Enterobius vermicularis* was investigated among students of a primary school and a kindergarten located in the rural area of Tangjin-gun, Chungchongnam-do in December, 1998. Of the 189 examinees, 28 (14.8%) were found to be infected with *E. vermicularis* by the adhesive cellotape anal swab method. The infection rates ranged from 4.2% to 26.1% among school children, and the highest rate was observed in children attending kindergarten. Three months after treatment with albendazole, four (14.3%) out of 28 infected children still remained infected with *E. vermicularis*. Through this survey, we were able to determine that *E. vermicularis* infection is still prevalent among children in rural areas of Korea.

negatives could have been undetected. It has been reported that 3 consecutive examinations with 4 to 5 day time intervals improved the detection rate of *E. vermicularis* from 50% to 87.5% (Kim et al., 1991). Since the life cycle of the parasite and children’s habits affect the control of *E. vermicularis*, a strict control or extermination of enterobiasis is difficult. Eggs of *E. vermicularis* have a short incubation period of about 6 hours in anus for hatching (Cram, 1943); therefore, infection from anus to mouth easily occurs. In more severe cases, retroinfection or vaginal invasion can be established. The family of an infected child should be treated at the same time, and underwears and bedclothes of the infected child should be sterilized (Garcia and Bruckner, 1997).

*E. vermicularis* infection seems prevalent in children of rural areas in Korea and there should be more extended survey for the infection status and adequate trials for treatment are required to provide better life conditions for school children.
